Abstract

Using equilibrium and nonequilibrium molecular dynamics simulations, we determine the Kapitza resistance (or thermal contact resistance) at a model liquid solid interface. The Kapitza resistance (or the associated Kapitza length) can reach appreciable values when the liquid does not wet the solid. The analogy with the hydrodynamic slip length is discussed.

1 Introduction: bulk and interfacial transport coefficients

One of the important issues of nonequilibrium statistical physics is the determination of transport coefficients, which relate the flux of conserved quantities to the gradient of the corresponding affinities. One of the simplest examples is the thermal conductivity defined macroscopically (in the absence of concentration or velocity gradients) by

$$\mathbf{j}_e = -\lambda \nabla T = \mathbf{L}_e \nabla \frac{1}{T}. \quad (1)$$

*Paper submitted to the special issue of Molecular Physics on the occasion of Dominique Levesque's 65th birthday, edited by J-P. Hansen and R. Lynden-Bell

[†]author for correspondance; barrat@dpm.univ-lyon1.fr

Here L_e is the Onsager coefficient associated with energy transport, $1/T = \partial S/\partial E$ is the affinity relative to energy.

Molecular dynamics, using either equilibrium or nonequilibrium methods, has proven a powerful tool for determining such coefficients, and, in fact, the only practical one when dealing with dense liquids. Equilibrium methods for systems with continuous potentials, pioneered by Levesque and coworkers [1], are based on the use of Green-Kubo formulae [2]. For the thermal conductivity, the formula reads:

$$\lambda = \int_0^\infty \langle \hat{j}_e(t) \hat{j}_e(0) \rangle dt \quad (2)$$

where $\hat{j}_e$ is a microscopic energy current that can be computed directly from the particle velocities and positions. The brackets refer here to an equilibrium average on the microscopic fluctuations *at equilibrium*. Green-Kubo calculations have the advantage that an equilibrium simulation can be used to determine simultaneously several transport coefficients. On the other hand, rather long simulations are required to obtain converged results for the time correlation function, and the determination of the 'plateau' of the Green-Kubo integral (as a function of the upper integration limit) is often difficult, since at long times the noise in the correlation function tends to produce a large numerical uncertainty.

A useful alternative for the determination of transport coefficients is provided by nonequilibrium molecular dynamics (NEMD) methods [3, 4]. In such methods, the system is driven into an equilibrium state using a modified MD algorithm, and the currents and gradients are measured directly in this state. Formally, these methods can be shown to be equivalent to the Green-Kubo equilibrium method as long as one remains in the linear response regime.

In both types of approach, one usually is interested in *bulk* transport coefficients, which are properties of the infinite, homogeneous system. Much less attention has been devoted to transport processes across interfaces between two bulk phases. At the macroscopic scales, the flux of a conserved quantity must be conserved across the interface. Continuum theories, however, usually assume continuity not only of the fluxes, but also of the affinities. The latter assumption, however, has no theoretical justification, and is only known to work 'in practice' at the macroscopic scale. A more consistent description of transport across an interface, in the spirit of usual hydrodynamic descriptions, allows for a jump in affinities between the two phases, proportional to

the flux of the conserved quantity. In the case of energy transport, such a phenomenological description can be translated mathematically as

$$\mathbf{j}_E \cdot \mathbf{n}_{12} = \frac{1}{R_K} (\mathbf{T}^{(1)} - \mathbf{T}^{(2)}). \quad (3)$$

To conform with usual notations, we have used the jump in temperature rather than the jump in affinity $1/T$. Equation 3 defines the *Kapitza resistance* R_K (or thermal contact resistance) of the interface, whose existence was pointed out by Kapitza in the context of liquid Helium physics in [5]. A more transparent definition can be obtained by defining the Kapitza length

$$l_K = R_K \lambda \quad (4)$$

where λ is the thermal conductivity of one of the phases (say phase (1)). l_K is simply the thickness of material (1) equivalent to the interface from a thermal point of view (see figure 1). The Kapitza resistance has been mostly studied in the case of superfluid Helium in contact with a solid, or in the case of grain boundaries between pure crystals [6, 7]. In both cases λ is large, so that the Kapitza length is large and measurable effects can be expected. Size effects on the thermal conductivity of composites are also an indirect way of assessing the thermal properties of interfaces. In the case of normal liquids in contact with a solid, however, it can be expected, on purely dimensional grounds, that l_K should be of the order of a few molecular sizes, and therefore not measurable.

In this paper, we show that l_K is indeed very small in the -most usual- case of a wetting (contact angle smaller than $\pi/2$) liquid-solid interface. In the nonwetting case, however, the coupling between the solid and the liquid is strongly reduced, and l_K can be increased considerably - reaching up to 50 molecular sizes.

Before we discuss in more detail the determination of l_K for a model liquid-solid interface, it is interesting to point out an analogy with another interfacial transport coefficient that has attracted considerable attention in the recent years, namely the 'slip length'. The definition of the slip length completely parallels that of the Kapitza length. In the bulk, the phenomenological equation relates the momentum flux (stress) to the velocity gradient (up to a factor of density, the velocity is the affinity relative to momentum). The transport coefficient of interest is the shear viscosity η , which in a simple, Couette flow situation is defined by

$$\sigma_{xz} = \eta \frac{\partial v_x}{\partial z} \quad (5)$$

Figure 1: Schematic illustration of the Kapitza length (left) and of the slip length (right) at a liquid solid interface.

where x is the flow direction and z the direction of the velocity gradient (see figure 1). At the interface, the tangential velocity is not continuous in general. Since v_x is zero in a solid at rest, the equivalent of equation 4 reads

$$\sigma_{xz}(z=0) = \kappa v_x(z=0). \quad (6)$$

Combining the two equations 5 and 6, one obtains a boundary condition for the velocity field

$$\frac{\partial v_x}{\partial z} = \frac{\kappa}{\eta} v_x(z=0) = \frac{1}{\delta} v_x(z=0). \quad (7)$$

Equation 7 defines the slip length δ , which is the distance over which the velocity field must be extrapolated inside the solid to obtain a zero velocity (see figure 1). In macroscopic hydrodynamics, δ is usually assumed to vanish, which amounts to a 'stick' boundary condition at the interface. However, with the development of accurate surface force measurement at the nanometer scale, it has become possible to measure nonzero values of δ . From a theoretical standpoint, it has been possible to determine δ (or rather the coefficient κ in equation 6) using a Kubo like formula:

$$\kappa = \frac{\eta}{\delta} = \frac{1}{Sk_B T} \int_0^\infty \langle F_x^{S \rightarrow L}(t) F_x^{S \rightarrow L}(0) \rangle \quad (8)$$

where $F_x^{S \rightarrow L}$ is the instantaneous force along x exerted by the liquid on the solid across the interface. It has also been shown, both theoretically and experimentally, that the wetting properties are an important ingredient in determining δ . Everything (lattice constants, densities) being otherwise equal, changing the solid-liquid interaction (and therefore the wettability) changes δ by orders of magnitude. Large (50 nm or more) values of δ have been measured for water on hydrophobic surfaces [8, 9, 10, 11].

Our model of the liquid-solid interface will be identical to the one used for our previous study of slip lengths. The interactions between species (i) and (j) are of the Lennard-Jones form

$$v_{ij}(r) = 4\epsilon \left[\left(\frac{\sigma}{r} \right)^{12} - c_{ij} \left(\frac{\sigma}{r} \right)^6 \right] \quad (9)$$

in which, for convenience, the strength of the attractive term is modulated by a coefficient c_{ij} , keeping ϵ and σ identical (obviously the same effect could be achieved by introducing different values of ϵ and σ ; in this form, emphasis

Figure 2: Transverse cut of a typical simulation cell. In order to avoid any possible problem with dissolution of solid atoms, those atoms are loosely bound to their equilibrium position through weak harmonic springs.

is put on the attractive part which is essential in controlling the wetting properties). For the liquid-liquid interactions, we set $c_{11} = 1.2$. For the FCC solid, $c_{22} = 1$, and the solid atoms are tethered to fixed lattice sites at a constant density, $\rho_s \sigma^3 = 0.9$, using weak harmonic springs. All interactions are cutoff and shifted at 2.5σ . The interfacial properties of the (100 FCC solid with the liquid have been studied in detail in reference [12]. By varying the coefficient c_{12} , it is possible to vary the contact angle θ , up to $\theta = 140^\circ$ for $c_{12} = 0.5$.

In the next two sections, we describe the methods used for determining the Kapitza resistance of this model interface. Results are presented in section 4.

2 Nonequilibrium molecular dynamics simulations

The setup used for computing the Kapitza resistance is illustrated in figure 2. A slab of liquid (typically of thickness between 30σ and 40σ), parallel to xOy is sandwiched between two layers of FCC solid of thickness $10 - 20\sigma$.

Figure 3: Temperature profile obtained for $c_{12} = 0.5$

The lateral dimensions of the cell, depending on the simulation, have been varied between 10 and 20σ . Periodic boundary conditions are applied in the x and y directions. Liquid densities are typically of order $\rho_l\sigma^3 = 0.8 - 1$, and the reference temperature is always $T = 1\epsilon/k_B$. The normal pressure P is obtained from the average force exerted by the liquid on the solid; all the simulations have been carried out at low values of the pressure, $|P| < 0.1\epsilon/\sigma^3$.

A temperature gradient is generated throughout the cell by coupling the upper and lower atomic layers of the solid to two thermostats at different temperatures. The thermostats use simple rescaling of the velocities for the group of atoms under consideration. When the two temperatures are different, a net energy flux j_E in the z direction results, which is computed by averaging the kinetic energy added (or removed) by each thermostat per unit time and surface. Temperature profiles are obtained from the local kinetic energy density.

A typical temperature profile obtained under these nonequilibrium conditions is shown in figure 3. In the 'bulk' liquid and solid, the temperature varies essentially linearly with position, in agreement with the predictions of Fourier's law. Note that a slight curvature is perceptible in the liquid phase, which reflects the dependence of λ on temperature. From the slope of the linear parts, the following values of the thermal conductivity in the bulk phases are obtained (all results are given in Lennard-Jones units, ϵ , σ , and

$$\tau = \sqrt{m\sigma^2/\epsilon};$$

$$\lambda_l(T = 1, P = 0) = 7.8 \pm 0.5 \quad ; \quad \lambda_s(T = 1, \rho = 0.9) = 8 \pm 1 \quad (10)$$

The liquid has a density $\rho_s\sigma^3 = 0.88$ at $T = 1$ and $P = 0$. The uncertainty on the results has two origins: first, the energy current is the nonzero average value of a strongly fluctuating quantity (i.e. the power extracted by the thermostats), and is therefore difficult to determine accurately. Our simulations, with a time step $h = 0.01$ and typically 10^6 steps, yield this quantity with an accuracy of about 5%. In the solid, the limited thickness makes the determination of the temperature gradient inaccurate, so that the uncertainty is somewhat larger than in the liquid.

Another issue concerning the solid thermal conductivity is the comparison of the phonon mean free path ℓ_{ph} with the thickness of the solid slab. Using $\lambda_s \simeq \ell_{ph}uc_v/3$ where u is the sound velocity (obtained from the equation of state) and c_v the heat capacity per unit volume, one finds $\ell_{ph} \simeq 2.5\sigma$. Therefore the thickness of the solid slabs is of order $3 - 4\ell_{ph}$, which means that ballistic effects in the transport of heat should be negligible. Indeed, we confirmed by some simulations using thicker solid boundaries (20σ) that the results were not sensitively affected by this parameter.

From the profile shown in figure 3 the Kapitza resistance is easily obtained by dividing the temperature jump (computed using the linear fits to the density profiles) by the energy flux. Note that a slight dependence of R_K on T is visible in figure 3. with a larger temperature jump on the 'warm' side. All results discussed in section 4 will correspond to the average values of R_K between the 'warm' and 'cold' sides, and therefore to a nominal temperature $T = 1$.

3 Equilibrium determination of R_K

A completely different route to the Kapitza resistance is provided by a Green-Kubo formula similar to that used for the slip length, equation 8. This formula, which to our knowledge was first written by Puech et al [6], reads

$$\frac{1}{R_K} = \frac{1}{Sk_BT^2} \int_0^\infty dt \langle q(t)q(0) \rangle \quad (11)$$

Here q is the energy flux across the interface of surface S , which is macroscopically defined by the surface integral $q(t) = \int \mathbf{j}_E(t) \cdot d\mathbf{S}$. Microscopically,

$q(t)$ is easily computed from the work per unit time exerted by the atoms belonging to the solid phase on those belonging to the liquid phase, namely:

$$q(t) = \sum_{i \in \text{liquid}} \sum_{j \in \text{solid}} \mathbf{F}_{ij} \cdot \mathbf{v}_i \quad (12)$$

Equation 11 can be justified through the following heuristic derivation. Let us consider a solid and a liquid coupled together through an interface of surface S . The total system (solid+liquid) is isolated, at equilibrium. For convenience, we will assume that the solid constitutes a thermostat (infinite heat capacity) at fixed temperature T_0 , while the heat capacity of the liquid part is denoted by C_V . If $E_l(t)$ is the internal energy of the liquid phase at time t , and if one assumes a Langevin evolution of this variable, one may write

$$\frac{dE_l}{dt} = q(t) = \frac{S}{R_K}(T_0 - T_l(t)) + f(t) \quad (13)$$

where T_l refer to the instantaneous temperature of the liquid. As usual in a Langevin description, we have separated the evolution of the slow variable (the energy) into a systematic contribution which would correspond to a macroscopic evolution and a random, δ correlated part $f(t)$. Writing $\langle f(t)f(t') \rangle = \gamma\delta(t-t')$, $X = E_l(t) - \langle E_l \rangle = C_V(T_l(t) - T_0)$ one may rewrite 13 in the standard Langevin form

$$\frac{dX}{dt} = -\alpha X(t) + f(t) \quad (14)$$

with $\alpha = \frac{S}{R_K C_V}$. Equation 14 is a standard Langevin equation for the variable X . The usual relations follow for the correlation functions

$$\langle X(t)X(0) \rangle = \frac{\gamma}{2\alpha} \exp(-\alpha|t|) \quad (15)$$

$$\langle q(t)q(0) \rangle = -\frac{d^2}{dt^2} \langle X(t)X(0) \rangle = \gamma\delta(t) - \frac{\alpha\gamma}{2} \exp(-\alpha|t|) \quad (16)$$

In the thermodynamic limit ($C_V \rightarrow \infty$) the second term vanishes, so that one may write:

$$\gamma = 2 \int_0^\infty \langle q(t)q(0) \rangle dt \quad (17)$$

Using the relations $\langle X^2 \rangle = \frac{\gamma}{2\alpha}$ which follows from equation 15 at $t = 0$, and the equilibrium distribution for X which yields the standard fluctuation

Figure 4: Time correlation functions for $q(t)$ for $c_{12} = 0.5$, $c_{12} = 0.8$, $c_{12} = 1$ (the surface of the cell is $S = 390\sigma^2$).

formula $\langle X^2 \rangle = \langle \delta E^2 \rangle = k_B T^2 C_V$, the Kubo relation 11 for R_K is obtained immediately from 17.

As usual [13], this line of reasoning can be extended to the 'generalized Langevin' case where the coefficient α is replaced by a memory kernel, and $f(t)$ is not a white noise. The Kubo formula is not modified, and the macroscopic transport coefficient being related to the time integral of the memory Kernel. The Langevin approach just consists in assuming a separation of time scales, so that the kernel can be replaced by a δ function with the appropriate intensity. Note, however, that the Kubo formula 17 holds only *after* the thermodynamic limit $C_V \rightarrow \infty$ has been taken. Hence, for a finite system, the running integral $2 \int_0^T \langle q(t)q(0) \rangle dt$ will consist of two parts: a first part yielding to a plateau value which contains the information on the Kapitza resistance, and a long time decay to zero. Typical correlation functions obtained in MD simulations (using the microscopic definition 12), and the corresponding time integrals, are shown in figures 4 and 5. The plateau of the time integral can be used for a determination of the Kapitza resistance.

Figure 5: Running integral of the time correlation function $\langle q(t)q(0) \rangle$ obtained for $c_{12} = 0.5$ and $P = 0.008$. A value of $R_K = 6.9$ results, to be compared with the value $R_K = 6.7$ obtained from a nonequilibrium simulation.

4 Dependence of R_K on wetting properties

It has been shown previously (see [12]) that the slip length at the liquid solid interface was dependent on the wetting properties. The ability of the solid to transfer momentum to the liquid is weaker when the liquid does not wet the solid, since in this case the liquid density is depleted in the vicinity of the solid wall. Obviously the same kind of effect could be expected in the Kapitza resistance, with a smaller rate of energy transfer when the liquid-solid interaction is weak. In order to check this expectation, we have studied, using both the nonequilibrium and the equilibrium approach, the Kapitza resistance of our model interface as a function of the interaction coefficient c_{12} , which also determines the contact angle. All simulations are performed at a pressure close to $P = 0$. The results are shown in figure 6, where it can be seen that the Kapitza length is indeed a decreasing function of c_{12} , with values close to a molecular size in the wetting case ($c_{12} = 1$), and values up to about 50 molecular sizes in the nonwetting case ($c_{12} = 0.5$). As a rule of thumb, l_K appears to be of the same order of magnitude as the slip length obtained in reference [12].

Figure 6: Kapitza length as a function of the interaction parameter c_{12} . All simulations are performed in the range of normal pressures $0.2 > P > -0.2$, where we have checked that the pressure dependence of l_K is weak. The error bars reflect the combination of several independent simulations (equilibrium and nonequilibrium) for determining each point. The heat conductivity of the liquid has been used to define the l_K from the Kapitza resistance.

5 Summary

In this paper, we have discussed the principles underlying the definition of interfacial transport coefficients, and shown, in the case of the Kapitza resistance, how such coefficients can be extracted from equilibrium or nonequilibrium simulations. Our results indicate that relatively large values of the Kapitza length can be obtained using standard (as opposed to superfluid) liquids, provided the liquid is not wetting the solid surface. Experimentally, it seems very difficult to measure directly this transport coefficient, as has been done for the slip length. However, R_K could probably be investigated by monitoring the heat conductivity of a porous matrix filled with liquid. Interfacial properties can then be tailored by treating the internal surface of the pores (e.g. grafting of short hydrocarbon chains to make the surface hydrophobic [14]).

Acknowledgments: the parallel MD code 'LAMMPS2001' developed by S. Plimpton (<http://www.cs.sandia.gov/~sjplimp/lammps.html>) was used throughout this work. All calculations were performed at the PSMN at ENS-Lyon and at the CDCSP of University Lyon I. Useful discussions with C. Cottin-Bizonne, P. Chantrenne and L. Bocquet are acknowledged.
